## 1 Abstract

Shot Boundary Detection, or simply Shot Detection, is a fundamental part of research in the broader field of video analytics, used for essential video analysis tasks such as video indexing and content-based video retrieval. For professional video game live streamers, who create hours of continuous content with significant downtime, identifying cuts in their streams is an important first step for automatically generating condensed stream highlights. In this project, I have summarized the nomenclature and methodologies established in the academic canon for Shot Detection research, implemented a sample of the most common approaches, Colour Histogram comparison and Edge Change Ratio using Canny Edge Detection, and compared their effectiveness when used on video game live stream content, as well as establishing methodological challenges to this new content form.

## 2 Acknowledgements

Thank you to my project supervisor Professor Prosenjit Bose for his help and direction throughout this project.

## 3 Motivation

### 3.1 Why Shot Boundary Detection?

With the proliferation of internet connectivity in recent years, there has been a massive increase in the volume of video on the internet. With this growth, an industry built around the creation, hosting and sharing of video content grew as well, with YouTube alone having an annual revenue of over US\$15 billion dollars [9]. Portable devices increase the accessibility for the creation and uploading of video content, and the combination of the massive social network surrounding content creation, with the enticing entertainment industry creating multi-millionaire content creators has exploded the sheer hours of video being uploaded daily. For YouTube, this type of content tends towards short-form video content at on average 10 minutes long. Comparing this to video game live streamers, who in some cases are live 8 hours a day, 5 days a week, and in some cases even more frequently, the volume of video uploaded per creator is significantly increased. In Q4 2019, there were 2.3 billion hours watched on Twitch, and 0.9 billion on YouTube Gaming [7].

For live streamers, when they have so much continuous uptime, it is important to create highlights of their daily streams, in order to increase their reach to viewers who don't have the time to watch their full time streams, as well as to diversify their brand onto a traditional YouTube channel. The creation of these highlights is extremely time consuming, as the hours of content must be sifted through manually by either the content creators themselves, adding hours to their daily workload, or by hired editors. Commonly, it is unfeasible for streamers to spend all their spare time manually editing highlight videos for their daily streams, and for streamers with a lower viewerbase and thus less income, it is also difficult to afford a full time editor. This creates another barrier of entry to the career of live streaming, a career track that is already difficult to get started in due to the high viewership required for career viability. The solution for this currently manual labour is an automated editing system, which methodologically identifies key scenes and removes downtime. This could use some implementation of technology analogous to Story Segmentation, which was a task for TRECVID 2003 [4], or using representative key frame extraction. However, for anything like Story Segmentation or key frame extraction to be possible, it is essential that the system first defines the video's scenes. To do this, we must find where scenes end, hence we use various shot boundary detection methods.

### 3.2 Cut Detection and Video Game Live Streaming

There has been significant research in the field of shot boundary detection over the past couple of decades, with multiple surveys of traditional shot detection methods [8] [10]. The shot boundary detection is a fundamental part of the broader field of video segmentation, which refers to the partitioning of video into spatial, temporal, or spatiotemporal regions that are homogeneous in some feature space. Video segmentation itself is an essential part of many video analysis problems, including, video summarization, indexing, retrieval, coding, authoring, and editing, as well as other applications in video surveillance and 3D motion and structure estimation with multiple moving objects [3]. There are many different aspects of the shot boundary detection problem, due to the fact that shot boundary's are can be defined by multiple different types of scene transitions - either an abrupt cut, or a gradual transition, such as a fade or a dissolve. These different transitions have different properties and patterns (see figure 1) that the shot boundary detection system must analyze, usually with each type of transition analyzed independently. For the purposes of this project, we will implement systems which detect abrupt cuts in video, and then apply these to systems to video game live stream clips.

Figure 1: Gradual Transitions: Their Differing ECR Values [8]

Additionally, there has been as far as I know at the time of this project, no research on the topic of video game live stream cut detection. It is understandable why - the video game live streaming industry is still very young, and the change in domain when compared to more typical edited video or film is significant. Rather than there being a typical film or video editor defining the end of each scene, we must analyze and formulate the typical "scenes" that define contiguous activity in video game live streams. This

project will examine the different possible approaches to defining scenes in video game live streams, and attempt to formulate a schema for which we can apply traditional cut detection techniques, as well as outline areas of potential new developments for specifically this area, similar to what has been done for sports television video segmentation.

## 4 Methodology

### 4.1 What is Video Game Live Streaming?

Video game live streaming is the activity of a person recording themselves playing a game to a live audience. Popularized in the mid 2010s primarily on Twitch, it started as just people who enjoyed playing games playing for people to build an audience and have fun playing games. By 2014, Twitch had more traffic than HBO's online streaming service [5], and it had begun to become more and more clear that the popularity of these live streams could generate significant revenue. As the community grew, so did avenues of revenue for streamers, and before long there were more than a handful of video game livestreamers generating significant income, with many more able to make a living off of streaming full time.

Currently, the profession of video game live streaming is appealing to many, but ultimately extremely inaccessible. This is due to the fact that a streamer must have an established and loyal community which supports the streamer with paid subscriptions through Twitch, donations, or via Patreon. Other sources of revenue include:

- Salaries from esports teams such as Cloud 9 or TSM, although these sponsorships are reserved for the most popular or skilled streamers.
- YouTube channels which host short form highlight videos. The problem with this was touched upon in the Motivation section, but to emphasize, it is very time consuming for streamers to manually curate highlights and create entertaining videos on top of streaming consistent hours to grow their community, and for new streamers who have jobs on top of their streaming, this becomes an insurmountable barrier of entry.
- Sponsored content, such as a game studio paying a streamer to play their game. Again, this type of revenue is only available to those select streamers who already have an established audience, as the paid content must be a viable investment to the sponsors.

This means that when a streamer is starting out, they must minimize their hours and keep a full time job, as it can take months or years before streaming income becomes viable full time. This leaves even less time for editing

highlights of streams for increased reach, which further limits the accessibility, of building the brand necessary to be successful as a professional live streamer, as discussed in the Motivation section.

## 4.2 What is Shot Boundary Detection?

We will begin by summarizing the problem of Shot Boundary Detection, and then we will take an overview of the formal schema for this problem as defined in Yuan et al. [10] and how they must be modified to fit into the video game live stream content format.

Shot Boundary Detection is the problem of how to automatically detect the beginning or end of a shot or scene, which for traditional film would be defined more precisely as an uninterrupted sequence of images captured by a single camera action. While the number of possible types of scene transitions is quite large, in practice, the vast majority of all transitions are either hard cuts, fades, or dissolves (at least when it comes to traditionally edited movies or video).

### 4.2.1 Defining a Cut in Video Game Live Streams

We will now define what we will use as cuts in Video Game Live Streams between two categories:

1. Scene transitions initiated by the streamer themselves, such as when they are transitioning from a full face camera to a game, or from game to game. Generally, these are specially made transitions that match the streamer’s branded overlay, and typically are fades or dissolves. Since these cover the whole screen and are similar in structure to conventional dissolves or fades in film, we will not be focusing on these types of transitions in this project.
2. Game transitions, i.e. transitions between different camera states in the game. Generally, in video games, there are three main camera states:
  - (a) Menus. Players begin the game on a menu called the main menu, where they select one of various options, then start the gameplay. Typically, the main menu is a simple straight up view of a series of possible selections. These views tend to be relatively static and are rarely areas of concern for false positives for any robust cut detection algorithm.

- (b) **Gameplay.** When players make their selection on the main menu, the game begins, which typically involves the camera shifting from the static menu display to a view of the player themselves. This view can have many different perspectives, but we will sum them up into two categories: Bird’s eye view, and first/third person view.

In the bird’s eye view, the camera sits in a fixed spot, observing the player and the area the player can maneuver in, which we will call the map. The camera only moves when the player is exploring an area of the map that is out of the scope of the current camera. Generally, for games that use these fixed birds eye view cameras, false positives are rare, as the backgrounds are relatively constant. Genres of games that have these birds eye view cameras include fighting games such as *Street Fighter*, and roguelikes such as *The Binding of Isaac*.

In the first/third person view, the camera is in the perspective of the player themselves, either showing the player what the player-character would literally see in the case of the first person view, or showing an over the shoulder view in the case of the third person view. Typical genres of games that have these views include first person shooters such as *Call of Duty*. In the case of games with these cameras, there is a serious problem with false positives, as there is significant camera movement whenever the player changes directions, which in practice is very frequently. These issues will be discussed more in the Results section.

- (c) **Cutscenes.** Many games use cinematic cutscenes as a way to progress the plot. In these cutscenes, the camera frequently breaks from the view more typical in the gameplay sections, utilizing camera techniques more reminiscent of film cameras.

Thus, we consider all transitions between the above three camera states as cuts, and we also include all cuts used in cinematic cutscenes as cuts.

### 4.3 Defining our approach to detecting cuts

For this section, we will follow closely the formal definition of shot boundary detection as outlined in Yuan et al [10], and we will describe our approaches to

these theoretical problems. Any detection technique consists of the following three core elements: the representation of visual content, the evaluation of visual content representation, and the thresholds for classifying discontinuity.

1. Representation of visual content: First we define  $f_i$  as the  $i$ th frame, where  $i \in 1..N$ , where  $N$  is the number of frames in the video. There are many different strategies for representing  $f_i$ , with the most straightforward being a direct analysis of each pixel value of the image. However, these data structures get extremely large as image resolution increases, and measuring dissimilarity becomes extremely more expensive as a result. A more popular approach is to extract some type of visual feature from each frame and condense our representation. More precisely, we must find a mapping from the image space  $Q$  to the feature space  $F$ , i.e. from frame  $f_i$  to the feature structure  $s_i \in F$ . There are many possible strategies for feature detection, but for the purposes of this project we will analyze the use of a colour histogram, as well as the Canny edge detection algorithm.

Our colour histogram functions as follows: We define our number of buckets  $B$ , which corresponds to a range of RGB values in each RGB channel. For our histogram, we use 8 bins, with each taking up 32 RGB values. Thus, we have an 8x8x8 3D array, and for each pixel in the image, we identify its RGB values, and place it in its appropriate bucket. We use 8 buckets to optimize the expense of the representation evaluation, balanced out with image accuracy. Having a low number of buckets also helps to reduce false positives caused by movement, as the small changes will be less pronounced as a full cut.

For our Canny edge feature structures, we simply use the Canny edge detection algorithm implemented in the Python OpenCV package. For more information on the Canny edge detection algorithm, see [1]. For our Hysteresis Thresholding, we use the values of 0 to 200, a relatively generous threshold, in order to detect as many edges as possible for our Edge Change Ratio.

2. Evaluation of visual content representation: In order to find cuts, we must calculate the discontinuity value between frames. To do this, we must calculate  $d_i \in 0..1$ , such that  $d_i$  is the discontinuity or distance between  $s_i$  and  $s_{i-1}$ . To do this, we experimented with multiple approaches, iterating through both unconventional attempts such

as the Structural Similarity Index for comparing Canny edge feature structures, to using established similarity/distance measures such as the Bhattacharyya Distance for measuring colour histograms, and the Edge Change Ratio for Canny edge features.

Bhattacharyya Distance is calculated as follows:

$$d_i(s_i) = \sqrt{1 - \frac{1}{\sqrt{s_i s_{i-1}} B^2} \sum_I \sqrt{s_i(I) \cdot s_{i-1}(I)}}$$

We calculate the Edge Change Ratio by:

- (a) Count number of edge pixels in  $s_i$  and  $s_{i-1}$
  - (b) Dilate and invert edges on  $s_i$  and  $s_{i-1}$
  - (c) Compute then count pixels out and in
  - (d) Reach our final result by taking the maximum between pixels out and in (see figure 2). [2]
3. Thresholds for classifying continuity: Finally, we must determine at what value of  $d_i$  means that  $f_i$  is a cut. There are many approaches to this problem, with some using a local threshold, which is determined by the contextual distance values in the region of  $f_i$  [11], and more recently neural networks have been employed to classify shots [6]. For the purposes of this project, however, we will use a global threshold, i.e. a fixed value which when exceeded by  $d_i$ , we consider  $f_i$  to be a frame on which a cut occurs. In order to determine the optimal global threshold for each type of media, we perform performance tests on each piece of media and report the results on the best performing global threshold.

Figure 2: Calculation graph of the Edge Change Ratio [2]

## 5 Results

Hello, here is some text without a meaning. This text should show what a printed text will look like at this place. If you read this text, you will get no information. Really? Is there no information? Is there a difference between this text and some nonsense like “Huardest gefburn”? Kjift – not at all! A blind text like this gives you information about the selected font, how the letters are written and an impression of the look. This text should contain all letters of the alphabet and it should be written in of the original language. There is no need for special content, but the length of words should match the language.
